DATA ACQUISITION, REDUCTION, AND ANALYSIS USING A MICROCOMPUTER

1. INTRODUCTION

Manual entry of data into a computer has been a significant problem since the invention of computers. In order to process data (in most cases), information must be typed into the computer. Manual entry of data is a laborious task when compared to reading data from a disk or receiving data from another electronic source. Many different types of electronic equipment are used to collect data from experiments. This equipment generates large amounts of data usually in the form of script charts or printed columns of numbers. Script charts are usually graphs of voltage versus time, and discrete data points must be measured and converted to a final result using correlations. This data is then manually entered into the computer for reduction and analyses. This report describes one method of eliminating the manual entry of test data. This approach applies to many data collection situations.

2. PROBLEM DEFINITION AND RESULTS

The problem encountered was the evaluation of the results of liquid dissemination tests of chemical munitions. A liquid-filled munition releases its contents over a grid on the ground. The information required from the test are the sizes of the liquid droplets that are disseminated. Witness cards are used to collect falling droplets. The witness cards are a statistical sample of the liquid falling on the grid. The stain diameters on the witness cards can be measured, and from this information droplet diameters, percentage of grid coverage, and mass liquid recovery may be calculated. The stain diameters of the droplets were measured using a commercial image analyzer, the Quantimet 900. The stain diameters may be used to calculate the droplet diameters which originally fell on the card. Several properties of the liquid droplets may be determined such as mass median diameter, mass mean diameter, and number median diameter. Dissemination tests can involve as many as 10,000 cards. The problem of card analysis was divided into two parts: (a) the analysis of the cards for spot diameters (stain diameters) and total number of spots, and (b) the analysis of the data to produce the desired information about the droplets produced in the test.

The current method of analysis reads the individual witness cards with an image analyzer. The spot diameter data is then manually entered into a computer for reduction. The image analyzer was built around a PDP-11 computer with a camera peripheral which enables a picture of a specific area of a card to be placed into the memory of the computer. The image is then manipulated by algorithms to determine the sizes and total number of spots on a card. The information generated for one card is printed out on one sheet of paper. Therefore, a test consisting of 10,000 cards would generate a rather large volume of paper. This process led to a large data entry job and was the major obstacle to obtaining useful results from the card data.

Two solutions to manual entry were available, but one solution proved more cost effective. The first solution called for procuring additional hardware and software from the manufacturer of the image analyzer. The image analyzer has two 8-inch floppy disk drives and was able to record card data; however, additional computer memory was required to do data reduction. In addition, a Pascal language compiler and system linker were required to write programs to run on the image analyzer. The total estimated cost for this solution is given below:

Memory Expansion Kit	\$4,000
System Linker	\$5,000
Pascal Compiler	\$3,000
Total	<u>\$12,000</u>

This \$12,000 was the minimum it would cost to reduce the raw data using the image analyzer. The programmer was restricted to writing programs which link into the existing image analysis program. In order to use the image analyzer as a true PDP-11 computer, an additional purchase of the RT-11 operating system would have been required.

The second solution was to find a way of interfacing the image analyzer to a computer so that data could be dumped to the computer. This solution was the cheapest way to collect and reduce the raw data using an external computer. The computer used was a desktop, \$3,000 microcomputer which uses the MS-DOS. There are some factors which were not evaluated for cost; but when you consider these factors, the second solution becomes even more appealing. These advantages of the second solution are:

- Since the microcomputer, its operating system, and the BASIC language were already known, the data reduction program could be written in a more direct manner compared to writing the same program for a foreign computer system.
- The microcomputer used 5 1/4-inch floppy disks which are standard for over 99% of all desktop computers using MS-DOS. The standard-sized disks allow easy interchange of data between microcomputers.
- The microcomputer could communicate with almost any other computer by means of an RS232 interface. Therefore, it could transfer data to computers which cannot read its disk format.

Writing a computer program in a known environment is two to three times easier; therefore, any costs incurred in writing a BASIC program could have been doubled or tripled if undertaken by the first solution. Using the first solution may have led to manual entry eventually if the raw or reduced data had to be transferred to an external computer or a central data storage site. By examination

of the above three points and the hardware costs, we see that the second solution has many advantages over the first solution.

The connection of the image analyzer to the microcomputer was accomplished by use of RS232 ports. The image analyzer uses an RS232 port to communicate to its printer. By analyzing the pin settings on the printer, the correct communication parameters could be determined. These parameters could be set by software in the computer. The only additional piece of hardware required was a smart cable. This cable basically interconnected the "receive" pin on the microcomputer with the "send" pin on the image analyzer. This was necessary because the microcomputer had an asynchronous port which would have connected the two "receive" pins. The printer was then connected to the microcomputer by means of a parallel port. In this case, the printer was able to function as either a serial or parallel printer. When data was dumped from the image analyzer, the data was received by the microcomputer and written directly to the disk drive. An optional hard copy could be received from the printer; however, this was not done since floppy disks are highly reliable, can be backed up, and reduce the risk of data loss. The hardware configuration is seen in Figures 1 and 2.

The factor which determines how easy or difficult the data collection and subsequent reduction will be is the power of the computer language employed. BASIC was used to write all programs connected with the image analyzer to date. The language allows for interrupts so that the computer could be doing data reduction while waiting for additional data to be sent from the image analyzer. Unfortunately, due to the massive amounts of data to be reduced, this feature of BASIC could not be capitalized on. A later version of this program could use this feature of BASIC. The following serial collection and data reduction scheme was devised. The flow chart in Figure 3 shows how the overall system of data collection and analysis functions. Appendix A contains the program listings.

The first block of Figure 3 represents data collection. In order to make this process as easy and error free as possible, the data collection program must be able to handle as many situations as possible. The program Takedata.asc (Figure A-2) does the following:

After the program disk is placed in Drive A and a format data disk is placed in Drive B, the computer is turned on and the program is automatically loaded into memory and searches for the raw data file on Drive B. If the raw data file is there, the program appends new data to the end of the file; otherwise, a new file is created. It is important to label disks because the program does not check to determine which disk has which test data.

While collecting data, the program generates a random pattern of ASCII characters on the monitor to let the operator know that the program is working correctly.

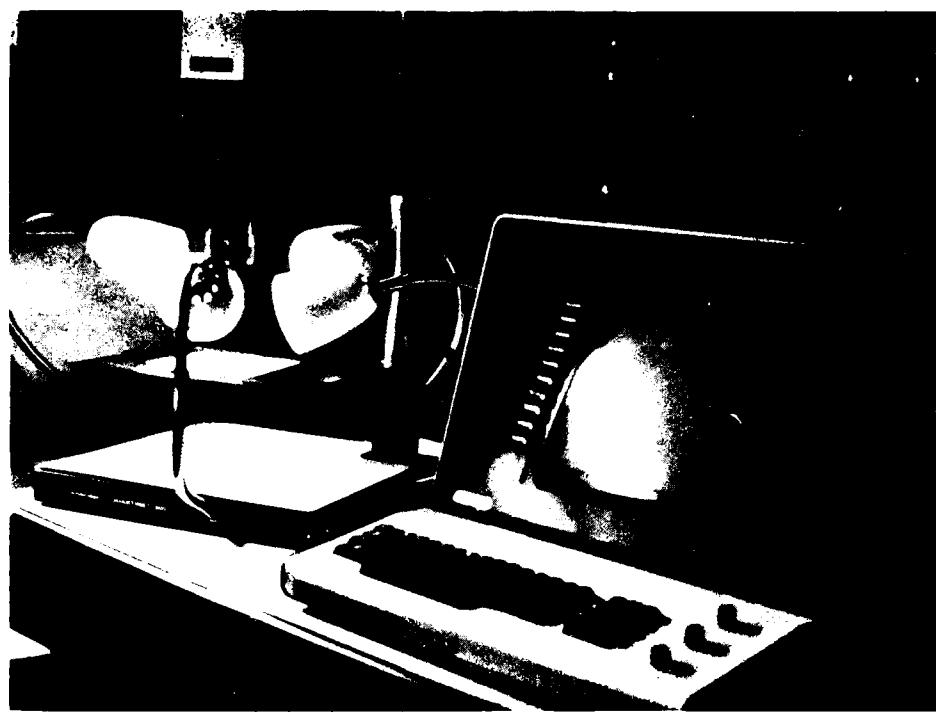

Figure 1. Image Analyzer Reading Dissemination Data Card

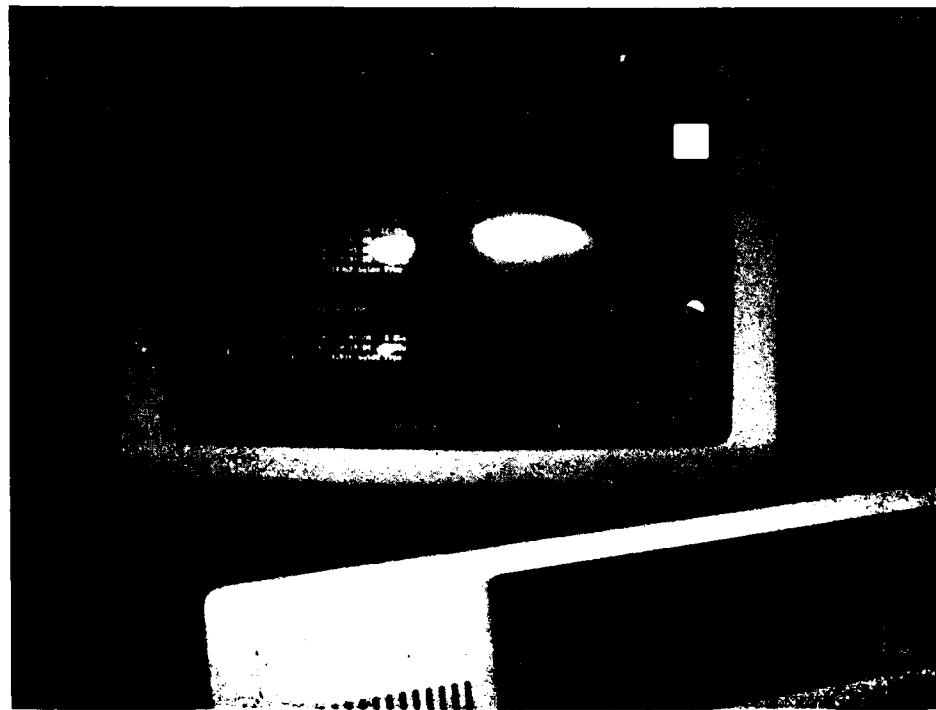

Figure 2. Microcomputer (IBM Personal Computer)

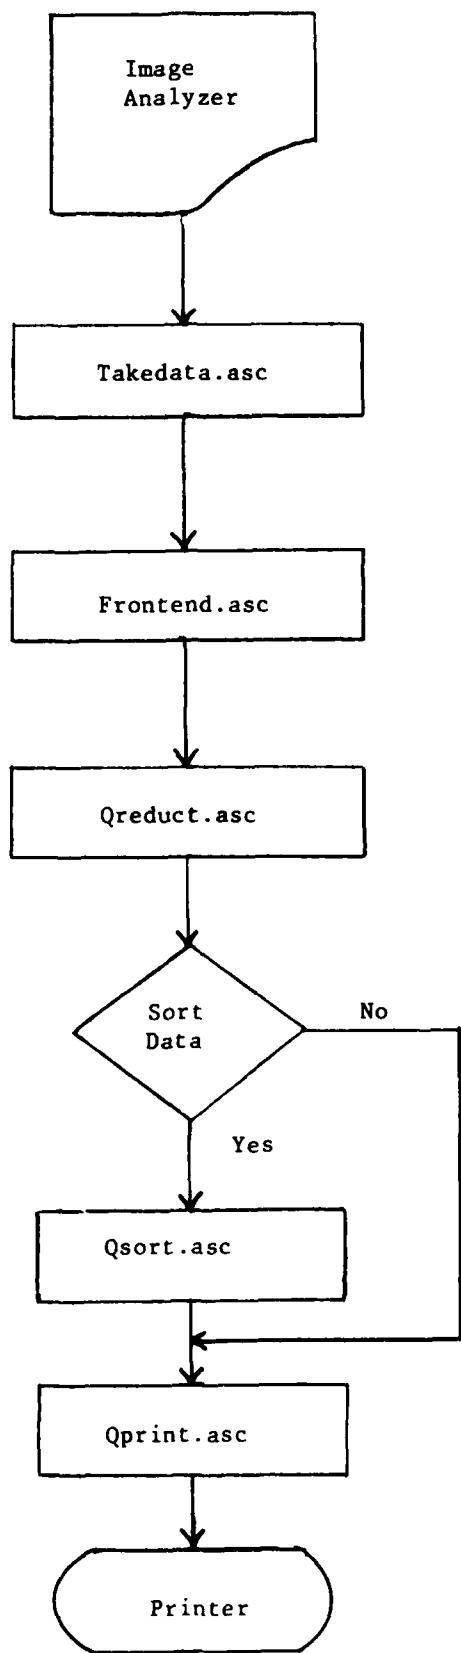

Figure 3. Flow Chart

Sequential card numbers are checked against one another to stop the reading of the same test card twice. If the same card is read again, the computer will alert the operator. In addition, if the operator enters an incorrect identification number into the image analyzer, the program will alert the operator to reread the card and enter the correct identification number.

The program also counts the cards read and will ask for a new data disk when the disk is full. These features are necessary because the operator can not be realistically tasked with entering data to both the computer and the image analyzer. The image analyzer was designed as a research instrument and not for working in a high-production environment. By entering data into the image analyzer and then transferring it to the computer, the goal of making the computer a data recorder, which does not require operator input, is achieved.

The second block in Figure 3 represents the initial phase of data reduction. In order for the computer to reduce data, the computer must have some information about the particular test; e.g., liquid density, constants of the stain diameter equation, and the test identification number. The stain diameter equation is a correlation between a diameter of a spot on a witness card and the actual diameter of the droplet which made the spot. The test identification number is used to create a file name for the reduced data. The program Frontend.asc (Figure A-3) creates a file with this and other test information.

The third block in Figure 3 represents the actual data reduction. The program Qreduce.asc (Figure A-4) reads the data file created by Frontend.asc and then generates the reduced data. The program first generates data about each individual card. If more than one data disk was used in data collection, the program prompts the user for the next data disk. Once individual card data is generated and written to Drive A, the accumulated size category data is written to Drive A. Finally, a file of overall test data is written to Drive A.

At this point, the user has a choice of sorting or not sorting data. This task depends on what is required and how the data was read initially by the image analyzer. If a circular grid was used in the dissemination test, the data may be sorted by radials (out from the source) or by zones (arbitrary distances from the source). The program Qsort.asc (Figure A-5) sorts data by zone and is included as an example of a sort program using the random file structure of Qreduce.asc. Depending on the grid used, each program user should write his or her own sort routine.

The fifth block in Figure 3 represents the printing of the reduced data. This program can print either sorted or unsorted data since it shares the same file structure as the previous programs. The program Printer (Figure A-6) prompts the user for background test data such as percent thickener, scan area, and liquid density.

This information is printed with the reduced data and raw data.
Appendix B shows a sample printout.

3. CONCLUSION

The solution chosen is cost effective and allows users to change their programs easily so that many approaches to data reduction may be used. The manual entry of image analyzer data into an external computer is eliminated. In addition, this method of interfacing computers to laboratory equipment can be expanded to almost any type of equipment which has a serial interface.
